THE VARIATION OF FLEXURAL RIGIDITY FOR POST-TENSIONED PRESTRESSED CONCRETE BEAMS

Ta-Heng Wang¹, Ran Huang¹, and Tz-Wei Wang²

Key words: natural frequency, prestressed concrete beam, softening.

ABSTRACT

The natural frequency of axial-loaded concrete beam decreases with increasing applied compressive force, and the natural frequency of tensioned cable increases with increasing tensile force. However, the variation of natural frequency of prestressed concrete beam (PCB) consisting of concrete and cable has rarely been discussed based on both the rigorous mathematic model and experimental results. In this study, a testing program was conducted and Rayleigh’s method was used to derive an approximate equation for computing natural frequency. The results indicate that (1) the natural frequency decreases with increasing prestressing force for PCB with eccentric parabolic tendon, but it is no change for PCB with eccentric straight tendon, (2) the proposed equation was proved to be an adequate method for estimating first mode natural frequency in vertical direction, and (3) a modified computed method for effective moment of inertia of PCB was also proposed.

I. INTRODUCTION

From the previous literatures [10, 12], the natural frequency $\omega_n$ in vertical direction for a simply supported beam subjected to an axial compressive force is computed as

$$\omega_n = \left( \frac{\pi}{l} \right)^2 \left( \frac{EI}{m} \right)^{1/2} \left( n^4 - n^2 \frac{P}{P_{cri}} \right)^{1/2}$$  

(1)

And for a cable stretched between two fixed ends with a distance $l$, the natural frequency $\omega_n$ of the cable is computed as

$$\omega_n = \frac{n}{2l} \left( \frac{T}{m} \right)^{1/2}$$  

(2)

where $l$ is the length of span, $EI$ is flexural rigidity, $m$ is mass per unit length, $P$ is compressive force, $P_{cri}$ is Euler buckling load, $T$ is the tensile force in the cable, and $n$ is the order number of vibration modes. The above-mentioned equations illustrate that the vertical natural frequency of concrete beam will decrease with increasing axial compressive force, and conversely the natural frequency of tensioned cable will increase with increasing tensile force. But only a few researches discussed the variation of the natural frequency for prestressed concrete beams (PCB) which are composed of concrete beam and prestressing cable.

Kanaka and Venkatesawa [9] formulated the natural frequency using Rayleigh-Ritz method for simply supported beam subjected to axial compressive force. The axial compressive force have significant effect on the lower mode vibration. In 1994, Saiidi [11] conducted a field bridge test and laboratory test. The natural frequencies and static vertical deflection were measured and it was found both natural frequency and effective rigidity decreased with decreasing axial compressive force. However, the testing results contradicted the theoretical prediction. He explained that the decrease of the natural frequency or effective rigidity could be due to the development of micro-crack resulting from prestress losses. His explanation induced 3 discussions. The discussions from Deak [5] and Jain [7] pointed out that an internal prestressing force would not reduce the natural frequency of PCB, but no experimental data or mathematical model were proposed to verify their hypothesis. The other discussion from Dall’Asta and Dezi [3] indicated that Eq. (1a) was proper to predict the natural frequency for concrete beam subjected to external force, but not for PCB. They proposed a modified Eq. (3) which was obtained by subtracting compressive stress from elastic modulus (E) to predict $\omega_n$ for PCB with axial prestressing force. Where $P$ is prestress force and $A$ is the cross section area of concrete beam.
Prior to 1994, the studies of natural frequency variation for PCB were focused on PCB with straight cable but without eccentricity. Until 1996, Dall’Asta and Leoni [4] used kinematic model to derive a complicated mathematical formulation for PCB with internal frictionless eccentricity curve cables. It was found that by increasing prestressing force, the natural frequency would decrease which was about equivalent to 10%~20% loss of elastic modulus. In 2006, Hamed and Frostig [6] derived a governing equation of motion for the dynamic behavior of PCB with bonded and unbonded tendons by using the variation principle of virtual work and Hamilton’s principle. His conclusion was opposite to some previous research results. He pointed out that the prestressing forces didn’t affect the dynamic behavior of PCB with bonded tendon and the natural frequency could be determined by linear elastic beam theory. But for PCB with un-bonded tendon, a modified model was proposed. In 2009, Breccolotti et al. [2] established a structural model which could be solved using commercial software ABAQUS 6.7. Breccolotti et al. [2] and Hamed [6] obtained similar conclusions. For PCB with unbonded tendon, the compression softening phenomenon was prominent, but not for PCB with bonded tendon.

From the aforementioned discussion, further study was needed to clarify the variation of natural frequency or rigidity for PCB due to internal axial stress. In this study, the natural frequencies before prestressing, after prestressing without grouting, and after grouting were measured for five post-tensioned PCB specimens. The P-Δ relationships were also monitored to evaluate the variation of flexural rigidity for bonded PCB. In addition, analytical results obtained from Rayleigh’s method were compared to the testing results.

II. EXPERIMENTAL PROGRAMS

1. Specimens

Five post-tensioned prestressed concrete beams were cast and tested. All the beams were designed with same geometric dimensions and steel reinforcement. For minimizing prestressing losses at transfer, BBRV wire post-tensioning system was selected. Two φ7 mm-coated stress-relieved wires which meeting the requirements of ASTM A421 were placed in a φ5 cm metal duct as prestressing tendon in each beam. The metal duct were grouted after prestressing. Three beams with parabolic curve tendon were stressed to 0.50, 0.625 and 0.75

\[ \omega_n^2 = \frac{\pi^2}{l^4} \left( \frac{E}{m} \right) \left( \frac{P}{A} \right) \left( \frac{P}{m} \right) \]

(3)

\[ \omega_n^2 = \frac{\pi^2}{l^4} \left( \frac{E}{m} \right) \left( \frac{P}{A} \right) \left( \frac{P}{m} \right) \]

Four beams with parabolic curve tendon were stressed to 0.50, 0.625 and 0.75 \(f_{pm}\) (equivalent to 31.4, 39.3 and 47.1 KN prestress force was applied) and were designated as P500, P625 and P750, respectively. The parabolic curve of tendon was designed with eccentricity \(e = 0\) at both ends and \(e = 8\) cm at center. Other two beams with straight tendon placed as a constant eccentricity of 8 cm were stressed to 0.50 and 0.75 \(f_{pm}\) (equivalent to 31.4, and 47.1 KN prestress force was applied) and were designated as S500 and S750, respectively. The average compressive strength of concrete was 25.48 MPa. Details of testing specimens are shown in Fig. 1.

2. Frequency Measurement

Piezotronics Model 086D20 impact hammer kits which including impact hammer, accelerometers, dynamic signal analyzer and display as shown in Fig. 2. were used to measure the frequencies of each specimen at three stages:

3. Load-Deflection Test

Load-deflection tests were conducted in the laboratory to estimate the flexural rigidity of specimens. The test set-up as shown in Fig. 4, each specimen was equally loaded at two points 115 cm away from supports. Three electronic gages connected to a data acquisition system were arranged under two loading points and middle point. Deflection was recorded at each 0.6 KN increment until failure. The load-deflection curves for five specimens are illustrated in Fig. 5 and partial curves are magnified as in Fig. 6 for estimating flexural rigidity of the uncracked specimen.

For predicting the immediate deflection after cracking, the effective moment of inertia, $I_e$, was suggested as Eq. (4) by ACI [1].

$$I_e = \left(\frac{M_{cr}}{2M_s}\right)^3 I_s + \left[1 - \left(\frac{M_{cr}}{M_s}\right)^3\right] I_{cr}$$

Where $M_{cr}$ is moment of inertia of gross section, $y_i$ is distance from central axis of gross section to tension face, and $M_s$ is maximum moment in member due to loading at stage deflection is computed.

Following Notes on ACI 318-95 [8], the moment of inertia of a cracked beam with tension reinforcement and prestressing

![Figure 4. P-A loading test.](image)

![Figure 5. Loading – deflection diagram.](image)

![Figure 6. Scaled up part of Fig. 5.](image)
tendon $I_a$ is computed in the following manner.

Taking moment of areas about neutral axis in Fig. 7

$$b \times c \times \frac{c}{2} = nA_p(d - c) + nA_{ps}(d_p - c)$$  \hspace{1cm} (5)

The moment of inertia of cracked section about neutral axis can be expressed as

$$I_{cr} = \frac{bc^3}{3} + nA_p(d - c)^2 + nA_{ps}(d_p - c)^2$$  \hspace{1cm} (6)

All of 5 specimens are designed with the same dimensions and amount of non-presstressed and prestressed steel which are $b = 16$ cm, $d = 26$ cm, $d_p = 23$ cm, $E_s = 28,200$ MPa, $E_c = 23,726$ MPa, $n = E_s/E_c = 8.48$, $A_{ps} = 0.772$ cm$^2$, $A_s = 5.7$ cm$^2$.

Solving Eq. (5)

$$c = 10.27$$

Substituting $c$ and above data into Eq. (6)

$I_{cr} = 18,791$ cm$^4$.

For each specimen, the immediate deflection curve (black line) computed with $E_c$ and $I_e$ which is obtained by substituting $I_{cr}$ into Eq. (4) is plotted together with testing load-deflection curve as shown in Fig. 8.

III. THEORETICALS

Rayleigh’s method is one of the methods for determining an approximate fundamental natural frequency. Since the system of simply support PCB is conservative, based on Rayleigh’s principle, the maximum kinetic energy $T_{max}$ is equal to the maximum potential energy $V_{max}$. By equating $T_{max}$ to $V_{max}$, the fundamental natural frequency $\omega$ can be found.

The kinetic energy of PCB can be expressed as

$$T = \frac{1}{2} \int_0^l \gamma^2 dm = \frac{1}{2} \int_0^l \gamma^2 \rho(x) dx$$  \hspace{1cm} (7)

Where $dm$ is mass of the element, $\rho(x)$ is mass per unit length, and $\gamma$ is harmonic moving equation assumed as $y = w(x) \cos \omega t$, then $\gamma(t) = -\omega w(x) \sin \omega t$. The term $w(x)$ is assumed as vertical deformed shape function of beam. Then the maximum kinetic energy can be expressed as

$$T_{max} = \frac{1}{2} \int_0^l (\gamma(t)_{max})^2 \rho(x) dx = \frac{\omega^2}{2} \int_0^l \rho(x)[w(x)]^2 dx$$  \hspace{1cm} (8)

By disregarding the work done by shear forces, the potential energy of the deformed beam can be expressed as

$$V = \frac{1}{2} \int_0^l M d\theta$$  \hspace{1cm} (9)

Where $M$ is the bending moment expressed by $M = EI \frac{\partial^2 w}{\partial x^2} = EI \frac{\partial^3 w}{\partial x^3} \cos \omega t$, $\theta$ is the slope of deformed beam, then $\theta = \frac{\partial w}{\partial x} \cos \omega t$ and $d\theta = \frac{\partial^2 w}{\partial x^2} \cos \omega t$. By substituting $M$ and $d\theta$ into Eq. (9), then

$$V = \frac{1}{2} \int_0^l \left( EI \frac{\partial^2 w}{\partial x^2} \right)^2 \cos^2 \omega t dx$$

$$= \frac{1}{2} \int_0^l \left( EI \frac{\partial^3 w}{\partial x^3} \right)^2 \cos^2 \omega t dx$$  \hspace{1cm} (10)

The maximum value of $V$ is

$$V_{max} = \frac{1}{2} \int_0^l \left( EI \frac{\partial^3 w}{\partial x^3} \right)^2 dx$$  \hspace{1cm} (11)

Let $T_{max} = V_{max}$, the fundamental natural frequency $\omega$ can be founded

$$\omega^2 = \frac{1}{2} \int_0^l \left( EI \frac{\partial^3 w}{\partial x^3} \right)^2 dx$$

$$= \frac{1}{2} \int_0^l \rho(x)[w(x)]^2 dx$$  \hspace{1cm} (12)

For simply supported non-prestressed concrete beams, The shape function in vertical direction $w(x)$ is assumed as Eq. (13),
\[ w(x) = K\left(l^3 x - 2l^3 + x^4\right) \]  

(13)

where \( K = \frac{\gamma_0}{24EI} \), \( \gamma_0 \) is unit weight of beam and \( x \) is the section position distance from the original point.

By substituting Eq. (13) into Eq. (12), the first mode of natural frequency \( \omega_1 \) can be found and expressed as Eq. (14).

Comparing Eq. (14) with Eq. (1) which use \( n = 1 \) and \( P = 0 \), the \( \omega_1 \) computed by Eq. (14) is very close to the value computed by Eq. (1).

\[ \omega_1^2 = \frac{V_{\text{max}}}{I_{\text{max}}} = \frac{3024EI}{31ml^4} = \frac{\pi^4 EI}{ml^4} \]  

(14)

For beams with parabolic pre-stressing tendons, an additional moments \( dM_p \) induced by pre-stressing forces at \( x \) as shown in Fig. 9 exists in the specified section. By force equilibrium,

\[ dM_p + (P_s + dP_s)(e(x) + de)\cos(\alpha(x) + d\alpha) \]

\[ -P_p e(x) \cos \alpha(x) - P_p \sin \alpha(x) dx = 0 \]

\[ dM_p = P_p e(x)\alpha(x)dx - P_p e(x)dx + P_p \alpha(x)dx - e(x) dP_p \]  

(15)

where \( P_p \) is prestressing force, \( dP_p \) is the change of prestressing force which will increase in one side and decrease in the other side for beams with symmetrical tendon and prestress at
both ends. Therefore the effects of \(dP_r\) will be vanished each other in the process of integration and can be neglected.

The term \(e(x)\) is the eccentricity of tendon at \(x\). For beams with parabolic tendon (P500, P625 and P750), the profile of parabolic tendons as shown in Fig. 1 is:

\[
e(x) = \frac{4e_c}{l^2} (x^2 - lx) = C(x^2 - lx)
\]

where \(C = \frac{4e_c}{l^2}\)

\[
\frac{de}{dx} = \tan \alpha = C(2x - l) = \sin \alpha = \alpha
\]

where \(\alpha\) is curvature of tendon profile

\[
\therefore \text{de} = \alpha \text{d}x
\]

\[
\frac{d\alpha}{dx} = \frac{d^2e}{dx^2} = 2C
\]

\[
\therefore \text{d}\alpha = 2Cd\text{d}x
\]

Then Eq. (13) can be derived as \(dM_p = 2C^3P_s(x^2 - lx)(2x - l)\text{d}x\), and the additional moment \(M_s\) at \(x\) is shown as Eq. (20)

\[
M_s = \int_0^x dM_p = P_s C^3(4x^4 - 4lix^3 + l^2x^2)
\]

Then the maximum potential energy \(V_{max}\) can be shown as Eq. (21). The first term in right side of equal sign in Eq. (21) is potential energy for beams without pre-stress, and the second term is additional potential energy due to pre-stress.

\[
V_{max} = \frac{1}{2} \int M(x) \text{d}\theta
\]

\[
= \frac{1}{2} \int_0^l EI[w^\prime(x)]^2 \text{d}x + \frac{1}{2} \int_0^l M_s w^\prime(x) \text{d}x
\]

\[
= \frac{12}{5} EIk^2 l^5 - \frac{3}{70} P_s C^3 K l^5
\]

The maximum kinetic energy \(T_{max}\) for PCB with parabolic tendons are un-changed. Based on Rayleigh’s principle, the first natural frequencies for PCB with parabolic tendons can be shown as Eq. (22).

\[
\omega_{n}^2 = \left(\frac{V_{max}}{T_{max}}\right) = \left(\frac{3024 - 1296P_s C^3 l^4}{31ml^4}l/\gamma_l\right)EI
\]

For beams (S500 and S750) with straight prestressing tendon, the profile \(e(x)\) as shown in Eq. (16) is constant. Then Eq. (11) \(dM\) is zero and the first mode of natural frequencies should be similar to natural frequencies of reinforced concrete beams.

IV. RESULTS AND DISCUSSION

1. Variation of Flexural Rigidity

To understand the variation of flexural rigidities for PCB, the first step is to determine the initial flexural rigidity \((E, I_0)\) of each specimen before prestressing. There are three initial flexural rigidities \((E, I_0)_{ACI}, (E, I_0)_{\omega}\) and \((E, I_0)_{\Delta}\) computed by three approaches listed in Table 2. Where \(I_0\) is moment of inertia of net cross section before grouting, \((E, I_0)_{ACI}\) is the product of \(E_{c}\) computed following ACI 8.5.1 and \(I_0\), \((E, I_0)_{\omega}\) is computed by measured first mode natural frequency following Eq. (1) or Eq. (14), \((E, I_0)_{\Delta}\) is the product of \(I_0/I_s\) and \((E, I_0)_{\Delta}\) which is the flexural rigidity computed by P-\(\Delta\) relationship before cracking for PCB after grouting (bonded). Both values of \((E, I_0)_{ACI}\) and \((E, I_0)_{\Delta}\) are used for comparing reference. Since the properties of concrete materials are non-homogeneous and shall be affected by the several uncertain factors as manufacturing process, curing conditions, and distribution of micro-cracks etc. Hence \((E, I_0)_{ACI}\) cannot represent the actual initial flexural rigidities. As for \((E, I_0)_{\Delta}\), these values derived from concrete beams had been prestressed don’t match the definition of initial flexural rigidities for
Slightly greater and closed to the values of \((E\omega_k\),\(\omega_1\)) following Eq. (22) with \(E\omega_k\), these two values are very closed just with 2~6% deviation (see column \(\varphi_1\)) in Table 3. This reveals that both \(\varphi_1\) and Eq. (22) proposed in this study are consistent with each other and letting \(\varphi_0\) in Eq. (5) and \(I_{cr}\) in Eq. (6) are independent of prestressed forces, then all the \(I_{cr}\) of specimens are the same. It seem unreasonable for PCB.

beams before prestressing. By comparing \((E\omega_k)_{uc}\) with these two reference values in Table 2, it shows values of \((E\omega_k)_{uc}\) are slightly greater and closed to the values of \((E\omega_k)_{uc}\), but far less than the values of \((E\omega_k)_{aci}\). Based on this comparison, values of \((E\omega_k)_{uc}\) are relatively reasonable as initial flexural rigidities for the following discussion.

Table 3 shows the variation of flexural rigidities for PCB prestressed before grouting (simulating PCB with unbonded tendon). Comparing \((E\omega_k)_{uc}\) as flexural rigidity computed by measured frequencies \(\omega_k\) following Eq. (22) with \((E\omega_k)_{aci}\), these two values are very closed just with 2~6% deviation (see column \(\varphi_1\)) in Table 3. This reveals that both \(\varphi_1\) and Eq. (22) proposed in this study are consistent with each other and letting \(\varphi_0\) in Eq. (5) and \(I_{cr}\) in Eq. (6) are independent of prestressed forces, then all the \(I_{cr}\) of specimens are the same. It seem unreasonable for PCB.

2. Effect Moment of Inertia for PCB

Comparing computed immediate deflection curve (black line) with testing load-deflection curve in Fig. 8, it reveals that computed deflection is always greater than testing deflection at the same loading. This results will over-optimistically assess the extent of cracking of PCB and lead to un-safety. Following Notes on ACI 318-95 [8], both of \(c\) in Eq. (5) and \(I_c\) in Eq. (6) are independent of prestressed forces, then all the \(I_c\) of specimens are the same. It seem unreasonable for PCB. It is well known that prestressing forces may constrain and postpone the development of cracking, so the \(I_c\) of PCB will be greater than \(I_c\) of reinforce concrete beam with the same amount of prestressing and non-prestressing steel but not prestressed. This study proposes force equilibrium method to compute \(c\) in Fig. 7 and use the same manner to calculate \(I_c\) in Eq. (6).
where \( f'c \) is concrete specified compressive strength of concrete, \( \beta_1 = 0.85 \) is factor relating depth of equivalent rectangular compressive stress block to neutral axis depth. \( f_y = 412 \text{ MPa} \) is specified yield strength of reinforcement, and according to ACI 318M-08 [1] the stress in prestressing steel at nominal flexural strength is taken as 0.55 for this study.

Substituting the calculating values of \( f_{ps} \) of Eq. (24) and \( c \) of Eq. (23) into Eq. (6), the proposed \( I_e \) are tabulated as Table 5. The immediate deflection curve (red line) computed following Notes on ACI 318-95 would over-estimate the non-linear immediate deflection of PCB. A force equilibrium method is introduced and the computed results are very closed to the testing results.

Note: The compressive strength of concrete of P500 is too low to failure before steel yield and \( I_e \) is taken as \( I_e' \).

0.85 \( f'c \beta_1 b \times c = A_f f'c + A_{ps} f_{ps} \) \hspace{1cm} (23)

where \( f'c \) is concrete specified compressive strength of concrete, \( \beta_1 = 0.85 \) is factor relating depth of equivalent rectangular compressive stress block to neutral axis depth. \( f_y = 412 \text{ MPa} \) is specified yield strength of reinforcement, and according to ACI 318M-08 [1] the stress in prestressing steel at nominal flexural strength is taken as 0.55 for this study.

2. Comparing the analytic results with testing data, Rayleigh’s method is proved to be a simple and useful method to calculate the first mode of natural frequencies for PCB. Similarly, for higher mode natural frequencies, Rayleigh-Ritz method which is an extension of Rayleigh’s method may be an effective method.

3. Eq. (4) which moment of inertia of cracked section is computed following Notes on ACI 318-95 would over-estimate the non-linear immediate deflection of PCB. A force equilibrium method is introduced and the computed results are very closed to the testing results.

Table 5. Moment of inertia of cracked section calculated by proposed method.

Note: The immediate deflection curve (red line) computed following Notes on ACI 318-95 would over-estimate the non-linear immediate deflection of PCB.

Where \( f_{ps} = 1,658 \text{ MPa} \) is specified tensile strength of prestressing steel, factor of type of prestressing steel \( \eta_p \) is taken as 0.55 for this study. \( \rho_p = \frac{A_{ps}}{bd_p} \), tensile reinforcement index \( \omega \) is taken as \( \frac{A_f f'c}{bd f'c} \), and compressive reinforcement index \( \omega' \) is taken as \( \frac{A_{ps}}{bd f_{ps}} = 0 \) in this study.

Similarly, for higher mode natural frequencies, Rayleigh-Ritz method which is an extension of Rayleigh’s method may be an effective method.

V. CONCLUSIONS

The findings from the testing program and theoretical analysis are summarized as follows:

1. No matter what post-tensioned PCB with bonded or unbonded tendons, natural frequencies (flexural rigidities) of PCB with parabolic tendons will decrease with increasing prestressing force. But natural frequencies (flexural rigidities) will not be affected by prestressing forces for PCB with straight tendons.
